Introduction

Inappropriate sinus tachycardia (IST) during pregnancy may be asymptomatic until maternal heart failure (HF) develops (1). There is no information on the safety of the use of ivabradine in pregnant patients.

Case Report

A 32-year-old patient, in the 17th week of her first pregnancy, was admitted to the local hospital with complaints of palpitations and shortness of breath, which progressed over a month. The patient had no prior history of any cardiac disease. At the time of admission, the electrocardiogram (ECG) of the patient revealed that she had supraventricular tachycardia. When the patient did not respond to adenosine and electrical cardioversion, she was transferred to our hospital. ECG revealed IST with a heart rate (HR) of 152 bpm (Fig. 1a). She was continuously monitored, and intravenous esmolol infusion and oral metoprolol were started. Due to the high HR, verapamil (240 mg/day) and digoxin (0.25 mg/day) were added, and HR decreased to 120 bpm (Fig. 1b). Echocardiography showed normal left ventricular (LV) dimensions, LV ejection fraction (LVEF) at 45%, and mild mitral regurgitation (MR). On the 7th day of hospitalization, LVEF decreased to 40%, followed by a decrease to 30% at the end of the 2nd week. The patient developed severe MR. Furosemide was added to the treatment, but the patient did not experience clinical relief. After receiving the patient’s consent, we began ivabradine treatment (2×5 mg), and the patient’s HR dropped to 90 bpm (Fig. 1c) and remained normal until discharge (Fig. 1d). Prior to ivabradine treatment, fetal echocardiography showed the fetal HR to be 156 bpm (Fig. 2a). After the 1st day of ivabradine treatment, the fetal HR was 150 bpm (Fig. 2b), and on the 7th day, it was 148 bpm (Fig. 2c). However, it did not decline further until delivery. When the patient’s HR returned to normal, LVEF improved each day and reached 50% and MR reduced. Maternal tachycardia and fetal bradycardia were not detected during the monthly follow-ups. A healthy baby boy was delivered. The baby was only fed with breast milk, and on the 15th day, ECG showed sinus rhythm with an HR of 180 bpm (Fig. 2d).

Discussion

Persistent IST is a rare atrial tachycardia characterized by an exaggerated increase in HR (usually ≥100 bpm at rest)
with “normal” P waves on ECG. P-wave morphology is usually similar or identical to sinus rhythm. In general, IST is a diagnosis made by exclusion. The treatment for IST has been limited to calcium channel blockers, beta-blockers, antiarrhythmic drugs, and sometimes, radiofrequency ablation. Although metoprolol, verapamil, and digoxin were used in maximum doses in our patient, the control of HR was not achieved and LVEF deteriorated each day, which led to the development of symptomatic HF.

The most popular choice for patients with drug-refractory IST is sinus node modification using radiofrequency ablation (2, 3). However, our patient did not agree to undergo the procedure because of risks such as ionizing radiation, phrenic nerve injury, requirement for permanent pacing, and pericarditis.

A specific HR reducing agent (through the inhibition of pacemaker If current), ivabradine has been documented to be effective for treating angina pectoris and HF (4, 5). The benefit of ivabradine in patients with drug-refractory IST has been described (3–6). There is no information regarding the safety of ivabradine use during pregnancy. In the literature, there is only one study by Babic et al. (7) that demonstrates the administration of ivabradine to a first-trimester pregnant patient presenting with myocardial infarction.

The success of ivabradine treatment for IST-associated cardiomyopathy has been reported in 2 patients in the literature (8, 9). With the improvement of tachycardia, the patients’ clinical symptoms and LVEF also improved, and reduction in MR was observed.

In rats, ivabradine has been shown to pass to the breast milk, but its effect is unknown (10). In our patient, the baby was only fed breast milk and neither bradycardia nor cardiac dysfunction was observed. Therefore, we concluded that ivabradine did not pass to breast milk in amounts that affect the baby’s HR.

Conclusion

We have shown that ivabradine treatment improved tachycardia and HF in a pregnant patient with IST-induced cardiomyopathy. In addition, no maternal and fetal side effects were observed. However, further studies are still needed to evaluate the use of ivabradine treatment during pregnancy and breastfeeding.

Introduction

Psoriasiform drug eruptions are very rare and generally characterized as erythematous, thick, dry, squamous, and demarcated plaques, resembling those of idiopathic psoriasis (1). Drugs may result in the exacerbation of pre-existing psoriasis or initiation of de novo psoriatic lesions (2). Apixaban, a reversible direct inhibitor factor Xa, is a novel anticoagulant, and its side effects mainly include clinically relevant major and non-major bleeding. Although <1% of patients receiving apixaban develop hypersensitivity reactions (including skin rash and anaphylactic reactions such as allergic edema) (3), there is no published case report demonstrating a psoriasiform drug eruption associated with apixaban. We report a psoriasiform drug eruption induced by apixaban.
