none of the patients underwent electrical cardioversion before the study recruitment. Finally, we agree with the comment that the data mentioned above should be stated in the text for precise evaluation of the disease- and the drug-related alterations in emotional status and quality of life.

Do spontaneous coronary artery dissections always need intervention in patients with no atherosclerosis?

To the Editor,

We have read the article entitled “Recurrent spontaneous dissection affecting different coronary arteries of a young female” written by Ermiş et al. (1) published in the February 2016; 16: 137-40 issue of the Anatol J Cardiol. It is very demonstrative and interesting article. The authors have reported the case of a 31-year-old female with recurrent spontaneous coronary artery dissections in different coronary arteries, who underwent multiple stenting and coronary artery bypass grafting (CABG).

The authors of this study have noted that the pathogenesis of the coronary artery dissection is not completely well understood. Several factors such as trauma, idiopathic etiology, smoking, and emotional stress are usually responsible for the etiology of spontaneous coronary artery dissections. Further, there is a tear between the intima and media, resulting in a false lumen, which leads to the compression of the true lumen; this in turn leads to distal myocardial ischemia, infarction, or sudden death. These dissections may usually heal spontaneously without any intervention, particularly, in moderate- or small-sized coronary arteries. However, they may also occlude the true lumen and lead to an acute coronary syndrome that may require a percutaneous coronary intervention (PCI) (2-4). There are some reports about the optimal treatment of spontaneous coronary artery dissections either by stenting and coronary artery bypass grafting or by conservative therapy (5-8).

In the present case report, the subject was a nonsmoker 31-year-old female with no typical chest pain and no atherosclerotic risk factors. There are some comments that need to be discussed. The authors noted that the electrocardiogram (ECG) showed an acute anterolateral myocardial infarction during admission; however, a figure of the ECG is absent. Further, coronary angiography revealed spontaneous dissection of the left anterior descending artery (LAD), involving a complete occlusion of the artery. There are some reports (9-10) regarding the spontaneous healing of the dissected arterial segments with conservative treatment, where a normal coronary flow may be restored. Coronary artery dissections in the mid and distal parts of the coronary vessels may be treated using a conservative approach. However, life-threatening and progressive dissections in the proximal part of the coronary vessels during the acute stage of the disease should be treated with PCI or CABG. It is important to decide which of the following treatments are best for treating spontaneous coronary artery dissections: angioplasty and stenting or conservative approach. Intravascular ultrasound (IVUS) and optic coherence tomography (OCT) are used to confirm the diagnosis of whether the condition is serious or not in the selected patients. IVUS or OCT could be useful in detecting intramural hematoma and relation of LAD and side branches in the presented case. On the other hand, PCI in coronary artery dissection may be associated with either failure of the procedure or complications with propagation of dissection that need to be treated with coronary stenting using a full metallic jacket covering of a long segment of the coronary artery or coronary bypass surgery. In the present case report, it can be considered that if a conservative treatment with heparin and nitroglycerin was administered for 24 or 48 h, the patient may not need multiple stenting or coronary artery bypass grafting surgery.

second episode, the patient suffered acute pulmonary edema treated with initial medical treatment; however, repeat angiogram showed persistent flow-limiting lesion, possibly caused by the intramural hematoma. Because of the life-threatening nature of this condition and hemodynamic instability, we were forced to consider the patient for CABG. In the third episode, the reason behind choosing PCI was the patient’s severe ischemia that was unresponsive to medical treatment and compromised hemodynamics, with TIMI I–II flow in the right coronary artery.

Moreover, we accept the role of adjunctive intracoronary imaging, such as optical coherence tomography (OCT) and intravascular ultrasound (IVUS), particularly in diagnosing SCAD subtypes, intramural hematoma, and localizing side branch/true lumen for the intervention (6). However, because of lack of IVUS or OCT facilities in our laboratory at that time, we could not use these techniques.

Effects of cardiopulmonary bypass on new-onset atrial fibrillation

To the Editor,

We read the article titled “SYNTAX score predicts postoperative atrial fibrillation in patients undergoing on-pump isolated coronary artery bypass grafting surgery” that is published in Anatolian J Cardiol October 18. Epub ahead of print (1), in which the authors described the effects of SYNTAX score on postoper-
