1 Introduction

Flexible mechanical systems are difficult to control since external disturbances cause variations on the system dynamics. These variations damage the performance of the control and lead to large tracking errors or damaging vibrations. Flexible link and joint manipulators with low stiffness coefficients are easily yawned under load change such that it brings extra-uncertainty and education problem compared to rigid manipulators. Therefore, in order to achieve high performance in the control of the flexible systems, designed controllers must compensate for the effect of the uncertainty. Thus, robust and high-performance controllers are in demand for flexible systems. Experimental flexible systems are introduced in literature [1, 2, 3] and some proposed controllers are offline-trained compensator [4], wavelet transformation-based iterative controller [5], minimum-time controller based on linear programming [6] and an extended observer-based controller [7].
filtered to enforce SPR condition then utilized to design controller in [18, 19]. In [20], the output control error is filtered to design the update rules and instead of adaptive observers, high-gain or sliding-mode observer-based controllers are proposed. Due to the singularity problem of control law, adaptive indirect controller is not preferable for the control of all nonlinear systems. Generally, a nonlinear system is assumed to be affine in Brunovsky form \( \dot{x}(t) = f(x) + g(x)y \) with a relative degree of 2. However, in the indirect adaptive controller design, there must be an additional assumption for \( g(x) \) function not to be zero which results relative degree 1 [21]. Therefore, some of the authors prefer direct adaptive controller which essentially approximates the controller dynamics [20] and some employ Nussbaum functions in indirect adaptive control [22, 23, 24, 25] for unknown controller direction.

Fuzzy function model is another reasoning scheme and representation of the fuzzy rules. General fuzzy function model is constructed with scalar inputs and their fuzzy membership values, both are functioned in the fuzzy regression matrix. The first fuzzy function least-squares model (FF-LSE) was shown to provide 10 better performance than standard LSE [26]. The applications of FF-LSE based models are given for regression, system identification [26, 27, 28, 29, 30] and pattern classification [31, 32]. A comparative work about rule based structures is given in [33] and a literature survey paper of the FF model with comparison to the other fuzzy systems is given in [34]. In addition, the fuzzy function model is extended using the type-2 fuzzy modeling concept [35]. Owing to the above developments, fuzzy function-based auto regressive with exogenous-input (FF-ARX) regressor models that structures the input measurements as scalars and also other ARX terms located in regression matrix in [27]. Consequently, known ARX linear modeling and fuzzy system nonlinear modeling abilities are unified to get better identification performance. Finally, a highly efficient FFARX model, which was introduced in study [27], is utilized for adaptive system identification and its convergence properties is detailed in [28].

In literature, adaptive fuzzy or neural-network observer-based controllers with Nussbaum functions (AFOBC) have been developed with various modifications for different applications. Based on the review of relevant literature, those controllers have the following advantages: (i) they employ the fuzzy modeling to approximate unknown system dynamics in adaptive control, (ii) the velocity measurement is not needed for reference tracking, (iii) Nussbaum function property is used to get rid of singularity problem. These are the main motivations to follow the literature works. In this paper, recently developed extended fuzzy function system [28] based indirect adaptive controller (EFFOC) is designed instead of using classical fuzzy system or neural-network. In simulation and real-time experiment, proposed EFFOC controller and classical AFOBC are compared in terms of design conditions and performances where the improved and not improved tracking performances are shown in the following results. Second contribution can be considered that to the best knowledge of the author, adaptive fuzzy function model and Nussbaum-gain techniques are first time used in the real time control experiment.

The remainder of the present paper is organised as follows. The theory of extended fuzzy function based regression and adaptive fuzzy function observer-based controller with Nussbaum functions are explained in Section 2. The numerical simulations including inverted Pendulum control comparisons are given in Section 3. In Section 4, a flexible joint manipulator is controlled via proposed and conventional adaptive controllers. Finally, the paper is concluded in Section 5.

2 Adaptive Extended Fuzzy Function State Observer-Based Control

In this section, fuzzy function regression, Nussbaum functions and adaptive observer-based controller methods will be explained.

2.1 Nussbaum Functions

Definition 1 [22] If a function has the following properties, then it is called Nussbaum-type function \( N(t) \):

\[
\lim_{t \to 0^+} \sup_{t > 0} \int_0^t N(t) \, d\tau = +\infty, \\
\lim_{t \to \infty} \inf_{t > 0} \int_0^t N(t) \, d\tau = -\infty.
\]

The Nussbaum functions are \( \xi^2 \cos(\xi) \), \( e^{\xi^2} \cos(\xi^2) \) and \( \xi^2 \sin(\xi) \) known in literature.

Lemma 1 [23] Let smooth functions \( V(t) \), \( Q(t) \) are defined on \([0, t_0] \) with \( V(t) > 0 \), \( \forall t \in [0, t_0] \), and \( N(t) \) be an even, smooth and Nussbaum-type function. If the following inequality holds:

\[
\frac{1}{2} V(t) \leq c_0 + e^{-\xi^2} \int_0^t g(s) \xi^2(s) \, ds + e^{-\xi^2} \int_0^t \xi^2(e^{\xi^2}) \, ds,
\]

where \( c_1 \) is a positive constant and \( c_2 \) is a constant. The \( g(s) \) is a time-varying parameter that it takes values in the known closed intervals \( I = \left[ i^-, i^+ \right] \) with \( 0 \notin I \), then \( V(t), q(t), \int_0^t g(s) \xi^2(s) \), \( \int_0^t \xi^2(e^{\xi^2}) \) are to be bounded on \([0, t_0] \).

The result given in Lemma 1 will be used to demonstrate the boundedness of the closed loop control signals such as states, tracking error, Nussbaum variables and functions. In this study, we use \( e^{\xi^2} \cos(\xi^2) \) type Nussbaum function.

2.2 Extended Fuzzy Function Modeling

Recently, fuzzy function based models have been used for accurate classification and regression problems due to its ease construction and high approximation capability. A simple FF-LSE model can be built by determining the parameters using only LSE and FCM clustering methods [26]. For that reason, FF-LSE model can be easily constructed and applied without much knowledge of the modeling of fuzzy systems. At first, FCM clustering is used to cluster the measured inputs and the cluster centers are used to design fuzzy systems. The measured inputs and fuzzy membership values are used in the fuzzy regression matrix. Then, the conventional LSE is applied to estimate the FF-LSE model parameters. The FF-LSE modeling is given as:

\[
\hat{Y} = \hat{\theta} \hat{\phi} + \varepsilon
\]

where \( \hat{Y} \) is the measured system output, \( \hat{\theta} \) is the vector of parameters, \( \hat{\phi} \) is the regression matrix. The residual \( \varepsilon \) is the modeling error. The FF-LSE model regression matrix \( \hat{\phi} \) is
designed as \( \psi = [1, X, b] \) where \( X = [u(1), u(2), \ldots, u(N)]^T \) is a \( N \times 1 \) complex input and \( b \) is its normalized fuzzy memberships. The FF-LSE model is designed as in the following items [26]:

1. Implement the FCM clustering algorithm and calculate the optimal membership values \( \mu_{ij}(k) \) of the measurement inputs \( \{x_i, y_i\} \) are determined from FCM. After that determine a threshold value alpha \( \alpha \) to disregard harmonics obtained via FCM [26], that increases the effect of the input values on the parameter estimation.

\[
\mu_{ij}(k) = \begin{cases} 
\mu_{ij}(k) & \mu_{ij}(k) \geq \alpha \\
\alpha & \mu_{ij}(k) < \alpha 
\end{cases}
\]

(4)

Then, the fuzzy membership values \( \mu_{ij}(k) \) are normalized as

\[
\gamma_{ij}(k) = \frac{\mu_{ij}(k)}{\sum_{i=1}^{m} \mu_{ij}(k)}
\]

(5)

where the \( m \) parameter is the predefined number of the input clusters, here the indices \( i \) and \( j \) are used for centers and inputs, respectively.

Finally, fuzzy least-squares 3D matrix \( \psi = [1, X, b] \) is utilized designating the measurement inputs and normalized fuzzy membership 3D clusters. The fuzzy basis function matrix \( b = [\gamma_{ij}]_{i=1, \ldots, n; j=1, \ldots, m} \) includes the normalized fuzzy membership values w.r.t. all cluster centers. Applying the one-step LSE method, the \( \theta \) parameters are calculated as

\[
\theta = (\chi^T \psi)^{-1} (\psi y)
\]

(6)

where \( \chi \) is the measured output of the system. A known superiority of the least-squares estimation is the one step ahead modeling that provides the optimum parameters from the measured input and output data. In fact, it provides a linear estimation in nonlinear feature space for FF-LSE modeling. Therefore, there is not required a nonlinear optimization method and resulting there is no local minima problem when the model parameters are estimated.

The above procedure is given for the offline FF-LSE modeling, then FF-LSE modeling was enhanced via incorporating the autoregressive with exogenous input model (ARX) and constructed different FF-ARX membership functions [27]. Following that using gradient-descent and recursive-least-squares modeling with adaptive learning rates, one of the superior membership functions in [27] is designed for online system identification and high performance of the online function approximation was obtained for different benchmark systems [28]. In this study, we apply the following fuzzy function model for online system identification in indirect adaptive control of nonlinear systems with unknown control direction. The regressor vector of the designed fuzzy function is given as

\[
\begin{align*}
\hat{u}(k) & = [u(k-1), u(k-2), \ldots, u(k-n)]^T, \\
\hat{y}(k) & = [y(k-1), y(k-2), \ldots, y(k-n)]^T,
\end{align*}
\]

(7)

where \( u(k-n), y(k-n) \) are the delayed inputs of the system, \( \hat{u}(k), \hat{y}(k) \) are the delayed outputs of the system, \( u(k-m), \hat{y}(k-m) \) are the delayed outputs of the system, \( \hat{u}(k) \) and \( \hat{y}(k) \) vectors are fuzzy basis functions which are normalized and filtered by alpha-cut.

### 2.3 Controller Design

Consider a single-input single-output \( n \times n \) order nonlinear system of the form

\[
\begin{align*}
x_1(k) & = x_2(k), \\
x_2(k) & = x_3(k), \\
x_3(k) & = f(x(k)) + g(x(k))u + d, \\
y(k) & = x_1(k),
\end{align*}
\]

(8)

where \( u \in \mathbb{R} \) is the control signal, and \( y(k), x_1(k), x_2(k), x_3(k), x(k) \) are the state vector, respectively. The \( f(x) \) and \( g(x) \) are the nonlinear and bounded smooth functions of the states, and \( d \) is the unknown external disturbance to the system. In order to design, a state observer based fuzzy function indirect adaptive control, the nonlinear system is represented as

\[
\begin{align*}
x(k) & = Ax(k) + Bu(k) + d, \\
y(k) & = Cx(k),
\end{align*}
\]

(9)

where

\[
A = \begin{bmatrix}
0 & 1 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0
\end{bmatrix}, \\
B = \begin{bmatrix}
0 \\
0 \\
0 \\
0
\end{bmatrix}, \\
C = \begin{bmatrix}
1 & 0 & 0 & 0
\end{bmatrix}.
\]

(10)

When the system dynamics (9) are known, a controller is designed to produce a control signal so that the nonlinear system can track a predefined reference signal \( \gamma = [\gamma_1, \gamma_2, \gamma_3] \). The output tracking error is described as \( e(k) = y(k) - \gamma(k) \), and the tracking error vector. It is defined with its \( n-1 \) derivative forms as \( \tilde{e}(k) = [e(k), e(k-1), \ldots, e(k-n+1)]^T \). The conventional feedback linearization controller [11,14,15] is described to remove the nonlinearity terms of the input-affine nonlinear system (8).

\[
\begin{align*}
u(k) & = \frac{1}{\lambda_0} f(y(k)) + \gamma_0(k) + K e(k), \\
\tilde{e}(k) & = [e(k), e(k-1), \ldots, e(k-n+1)]^T \quad (11)
\end{align*}
\]

(11)

where \( K = [K_1, K_2, K_3] \) when \( d = 0 \). Substituting (11) into (8), then a closed loop control system dynamics is governed by

\[
\tilde{e}_0 + \lambda_0 \tilde{e}(k) \quad (12)
\]

where the constants \( \lambda_i, i = 1, 2, \ldots, n \) are suitably selected parameters to make \( A - BK \) polynomial strictly Hurwitz. Then, we have \( \lim_{k \to \infty} \tilde{e}(k) = 0 \), where it results that the system output tracks asymptotically to the defined reference signal.

The \( f(x) \) and \( g(x) \) nonlinear system functions of the system are not known and approximated adaptively by the designed fuzzy function model. Using \( e(k) = x(k) - \gamma(k) \), the tracking error dynamics are obtained as

\[
\begin{align*}
\dot{e}_i & = Ae + Bu(k) + c_i e_i, \\
\tilde{e}_0 & = C^T e.
\end{align*}
\]

(13)

where \( \gamma_i = \lambda_i y_i + \lambda_i y_i \) adaptive fuzzy function observer-based control design, the tracking problem is converted to design a state observer of tracking error such that the state observer essentially estimates the tracking error [15]. The state observer is given as

\[
\begin{align*}
e(k) & = (A - BK) e + \bar{K}_0 e + \bar{K}_0 e, \\
e(k) & = (A - BK) e + \bar{K}_0 e + \bar{K}_0 e
\end{align*}
\]

(14)

with the observer feedback gain vector \( K = [K_1, K_2, K_3]^T \in \mathbb{R}^n \) and \( e = x - \gamma = [e_1, e_2, e_3]^T \in \mathbb{R}^n \). In state observer design, the couple \( (C, A) \) must be observable. The \( K \) can be chosen so that the \( A - BK \) polynomial of the observer is strictly Hurwitz. The observer error dynamic \( e(k) = e(k) - e(k) \) is derived as \( e(k) = (A - K_0 C) e - \gamma_0 + f(x(k)) + e(k) + g(x(k))u + d \). Using \( f(x) = f(x) + e(k) + g(x(k))u + d \), the \( f(x) = f(x) + e(k) + g(x(k))u + d \) is the optimal approximation of the function with minimum approximation error \( \gamma \). For the \( g(x) \) function part of the system, instead of approximating the \( g(x) \) function, we approximate 1/\( g(x) \) function using Nussbaum functions not to reduce degree of freedom when unknown control direction.
exists. In both cases, \( g(x) \) function approximation causes a modeling error as given in (15).

To design a observer-based stable indirect adaptive controller, the transfer function of the linearized nonlinear dynamics must satisfy the SPR condition (14). In order to satisfy SPR condition, the fuzzy basis functions are filtered in [12, 15]. However, the filtering the large dimensioned fuzzy regressor vector is not feasible in real time applications, therefore the filtering of estimation error is proposed in [16, 10]. Therefore, same approach is used to obtain a suitable SPR transfer function here. The proposed filter is

\[
L(x) = \left( \frac{\omega_i}{\omega_{i}} \right)^{\alpha}
\]

where the filter design parameter is chosen \( \alpha > 0 \), \( s \) is the Laplace parameter and \( n \) is the system order. Using the filter above, the observer error dynamics are filtered as

\[
e_\varepsilon = A_e e_\varepsilon + B[K_d e_\varepsilon - y_r] + \theta_\varepsilon T \psi(x) + \hat{g}(x)u + e_\varepsilon,
\]

where

\[
e_\varepsilon = \theta_\varepsilon \left[ 27 \theta_\varepsilon \phi(x) + (\hat{g}(x) - \bar{g}(x)) \right] + A_e \hat{e}_\varepsilon + B[K_d e_\varepsilon - y_r] = \left[ 1 \right]_0 \theta_\varepsilon \phi(x) + \hat{g}(x)u + e_\varepsilon,
\]

and \( e_\varepsilon = [0 \ 0 \ ... \ 0] \). From (9), the \( \theta_\varepsilon \) is the estimated optimal parameter vector which is given by

\[
\theta_\varepsilon = \arg \min_{\theta} \left[ \left| \theta \right|^2 \right].
\]

Assumption 1 [15]: The following closed-loop signals are the unknown external disturbance as \( |d(t)| < d^* \), the \( (\hat{f} \) function approximation error as \( |\hat{f}(x)| < f^* \), the estimated optimal parameter vector as \( |\theta_\varepsilon| < M_\varepsilon \). Therefore, the filtered uncertainty of the approximation is bounded as \( |\hat{e}_\varepsilon| < e_\varepsilon \).

The given assumption is reasonable to limit system uncertainties in closed-loop control dynamics. The universal approximation theory permits to bound approximation error since the disturbance has a bound. The approximation error between filtered signal and real signals is bounded at the moment since the parameter vectors are bounded.

Theorem 1 For the system (8), under Assumption 1, an adaptive fuzzy control system observer-based controller is designed as

\[
\hat{U} = N^T(x)\hat{f}(x) + K_d \hat{e}_\varepsilon + \theta_\varepsilon \phi(x) + \hat{g}(x)u + e_\varepsilon,
\]

with parameter adaptation law

\[
\dot{\theta}_\varepsilon = \gamma e_\varepsilon \phi(x),
\]

and robustness input

\[
\nu = -\varepsilon \phi(x),
\]

such that the nonlinear system (9) tracks the reference signal \( y_r \) and the closed-loop signals in the remain bounded.

Proof: The Lyapunov function is selected as

\[
\dot{V} = \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} \theta_\varepsilon^T P \theta_\varepsilon + \frac{1}{2} \hat{g}(x) \hat{g}(x)^T \bar{g}(x) - \frac{1}{2} \hat{g}(x) \cdot \hat{g}(x)^T \bar{g}(x) - d^*(\hat{f}(x) + \theta_\varepsilon \phi(x)) - d^* e_\varepsilon.
\]

For a system with SPR transfer function (14), there exist \( P = P^T > 0 \) \( \in \mathbb{R}^{n \times n} \) matrix with given \( Q = Q^T > 0 \) which satisfying Lyapunov equation

\[
A^TP + PA = -Q,
\]

and substituting the observer error dynamics (17) in (24) yields

\[
\dot{V} = \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} \hat{g}(x) \hat{g}(x)^T \bar{g}(x) - \frac{1}{2} \hat{g}(x) \cdot \hat{g}(x)^T \bar{g}(x) - d^* e_\varepsilon.
\]

According to (22) and using \( \hat{\theta}_\varepsilon = \theta_\varepsilon - \bar{\theta}_\varepsilon \) and \( \hat{\gamma}_\varepsilon = -\hat{\gamma}_\varepsilon \) Lyapunov function derivative is

\[
\dot{V} = \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} \hat{g}(x) \hat{g}(x)^T \bar{g}(x) - \frac{1}{2} \hat{g}(x) \cdot \hat{g}(x)^T \bar{g}(x) - d^* e_\varepsilon.
\]

From the parameter adaptation law \( \frac{1}{2} \theta_\varepsilon^T - \gamma e_\varepsilon \phi(x) \hat{g}(x) = 0 \).

Substituting the control signal \( u \)

\[
\dot{V} = \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} \hat{g}(x) \hat{g}(x)^T \bar{g}(x) - \frac{1}{2} \hat{g}(x) \cdot \hat{g}(x)^T \bar{g}(x) - d^* e_\varepsilon.
\]

Using the minimum value of \( \theta_\varepsilon \), \( a = \lambda_{\min}(Q) \),

\[
\dot{V} = \frac{1}{2} e_\varepsilon^T Pe_\varepsilon + \frac{1}{2} \hat{g}(x) \hat{g}(x)^T \bar{g}(x) - \frac{1}{2} \hat{g}(x) \cdot \hat{g}(x)^T \bar{g}(x) - d^* e_\varepsilon.
\]

0 \leq V(t) \leq e^{-d^*V(0)} + e^{-d^*t} \int_0^t e^{-d^*s} \psi(x(s)) ds dt \leq d^* e^{-d^*T}\int_0^T e^{-d^*s} \psi(x(s)) ds dt \leq d^*

Definition 1. [36] A \( \psi(x) \) is a fuzzy basis vector which is excited persistently, if \( \kappa > 0 \) and \( T_0 > 0 \) constants exist such that

\[
\int_0^T e^{-d^*s} \psi(x(s)) ds dt \leq \kappa T_0 \forall t \geq T_0.
\]

The persistent excitation is satisfied at the same time for EFF system due to Gaussian membership functions and \( a > 0 \) constant (4).

3 Numerical Simulations

The proposed (EFFORC) controller and conventional (AFORC) [10] have been first been designed and applied to control an inverted pendulum and numerical simulations are given Figure 1 and in Table 1. The inverted pendulum is well known highly nonlinear and originally unstable system without any control input. The following equations of inverted pendulum motion can be derived as summing the forces acting on the pendulum system:

\[
x_1(t) = x_2(t),
\]

\[
x_2(t) = \frac{1}{mL^2} [ -b \sin x_1(t) \cos x_2(t) - mL \sin x_2(t) \sin x_1(t) ]
\]

where \( x_1 \) is the position of the pendulum and \( x_2 \) is the pendulum angular velocity. The experiments are performed
using a 4th Runge-Kutta integration routine and the sampling period is selected as $10^{-3}$ seconds. The initial parameters of fuzzy systems are determined as linearly-spaced from the interval $[0,1]$. Gaussian membership functions are utilized with constant centers and standard deviations. The centers are selected as linearly-spaced between $[-1,1]$ that are the min-max values of the position, respectively, and standard deviation is selected as 0.1. The variable of Nussbaum function is designed as zero. The filter parameter of the observer is chosen as 10. The adaptive controller feedback constants are $K_e = [100,200]$ and observer gains are chosen as $K_o = [400,40]$. The number of the centers for input and output memberships are selected as $R = 10$ which is corresponding to the number of the rules. The $\alpha$ value of equation (4) is chosen as 0.65. These parameters are selected via grid search of relevant intervals.

The proposed EFOBC and AFOBC [10] are initialized with same parameters and fair comparisons are made to show accuracy of the proposed controller. There is another work which proposes a new SPR filter based adaptive fuzzy control (AFSPR) control includes pendulum tracking performances. It must be noted that the initial parameters or other parameters of AFSPR are not same with EFOBC. However, in order to assess the accuracy of pendulum tracking, the same performances are given and compared in Table 1. The integral of squared-error (output-tracking) and integral of required input signal's absolute error (IAE) are used to compare the designed controllers [11].

In fact from the literature, it is known that the fuzzy function modeling itself improves the function approximation capability 90% better than classical fuzzy model [26, 28, 33]. However, the fuzzy function modeling inside indirect adaptive control (EFBC) provides approximately 90% better IAE and ISE performances than classical indirect adaptive fuzzy control (AFOBC) which partly supports the previously obtained literature results. The reason to be indicated that the controller parameters and observer performance predominantly affect the tracking performance than the identification performance.

4 Experimental Verifications

In order to illustrate the capability of designed controllers EFPOBC and AFPOBC, flexible joint manipulator (FJM) [3] has been controlled in real-time experiments. The manipulator is shown in Figure 2. Its approximate mathematical model [3] is

\[
\dot{x}(t) = \frac{k_r}{I_{eq}} x(t) + \frac{k_v}{I_{eq}} \dot{x}(t) + \frac{1}{I_{eq}} u(t)
\]

\[
\dot{\theta}(t) = \frac{1}{J_1} \frac{I_{eq}}{J_{eq}} x(t) - \frac{1}{J_{eq}} \theta(t) - \frac{1}{J_{eq}} u(t)
\]

where \(x(t)\) is the angle of the servomotor and \(\dot{x}(t)\) is the velocity, respectively. Then, \(\theta(t)\) and \(\dot{\theta}(t)\) are the position and the velocity of the manipulator, respectively. The numerical values and definitions of the parameters are as follows.

- \(k_r = 0.004\) Nm/(rad/s) is the damping coefficient.
- \(b_{eq} = 2.00 \times 10^{-3}\) kg.m/s is the inertia of the motor.
- \(K_v = 1.24\) N.m/deg is the stiffness coefficient.
- \(J_1 = 3.9 \times 10^{-3}\) kg.m² is the inertia moment of the arm.

The flexible joint manipulator is a well-known experimental system which is utilized to test different control methods [6, 7]. The above system model is derived based on the constant end-effector mass assumption. However, we can add an external mass to the end of manipulator to carry a varying payload. Therefore, the robot manipulator dynamics must be modified by adding a \(m_{z_{eq}} g \sin(\theta)/J_{eq}\) term for model-based controllers such that linear controllers with constant parameters are not suitable for this experiment. However, the effect of payload variation is not required to be elaborated separately due to the nature of adaptive controller capability.

In this experiment, the input-output function relation is assumed to be between the position of payload and the input-voltage applied to the servomotor of manipulator.

Table 2: Real-time performances.
The flexible-joint manipulator is controlled to track the time-varying reference signals. The experiments are performed same as using a fourth-order Runge-Kutta integration routine and the sampling period is selected as $10^{-3}$ seconds. The extended fuzzy function system parameters are initialized between linearly-spaced $[-1,1]$. Gaussian membership functions are utilized with constant centers and standard deviations. The centers are linearly-spaced between $[-0.7,0.7]$ that are the min-max values of the position, respectively, and standard deviation is selected as 0.1. The variable of Nussbaum function is initialized as zero. The filter parameter of the observer is selected as $\bar{x}$. The adaptive controller parameters are $k_i = [30,11]$ to locate closed-loop poles at $-5$ and $-6$. Then, the observer gains are chosen as $k_i = [800, 60]$ to locate observer poles at $-20$ and $-40$. Using these constants and initial parameters, the adaptation of parameters is continued and manipulator is positioned to the different-type of signal references. The number of the centers for input and output memberships are selected as $n = 10$ which is corresponding to the number of the rules. The value of equation (1) is chosen as 0.05. These parameters are selected via grid search of relevant intervals. The same initial parameters are utilized in conventional AFOBC design for fair comparisons.

The experiment results are shown in Figure 3. Figure 2 represents the manipulator positions such as very accurate tracking is obtained for all references. The tracking errors seen in Figure 2 are very small except the reference signal changes sharply. Figure 2 indicates the estimated velocity of the manipulator such that it is employed to produce control signal in feedback control law. Finally, the generated control signal is given in Figure 2. The real-time control comparisons are given in Table 2 which includes RMSE and IAE performances. From the real-time experiments, there are obtained $97\%$ RMSE performance improvement and $97\%$ IAE performance declension. It can be explained as due to the linear input-output terms of the regressor vector cause fast parameter adaptations and sharp input changes.

5 Conclusion

In this paper, an adaptive extended fuzzy function state observer-based controller (EF0BC) was proposed for a class of nonlinear unknown systems. The proposed EF0BC and conventional AFOBC were designed to control an inverted pendulum in simulation and a flexible-joint manipulator in real-time experiment. In numerical simulation using EF0BC with selected optimal parameters, $96.10$ IAE performance improvement was provided. In real time experiment, RMSE of tracking was improved $96\%$ compared to conventional AFOBC. More importantly, due to the employed Nussbaum-gain technique, it is possible to position the payload at all angles of the flexible manipulator with unknown system dynamics. The application results are compared with the theory explained in the paper and it can be concluded that the proposed controller methodology can be used to control flexible systems to a satisfactory level of tracking performance.
