Abstract
Spontaneous acute pneumothorax may occur as a result of spontaneous rupture of subpleural blebs or bullae and it is extremely rare during pregnancy. Bilateral pneumothorax and pneumomediastinum were detected in a young pregnant woman admitted with the complaints of swelling and pain on her neck and upper thorax following 2 days of dyspnea. Nasal oxygen, analgesics and antiemetics were used as needed during ten days of hospitalization. Physical findings, chest x-ray and oxygen saturation improved at the end of this period. Since supportive treatment was sufficient, invasive treatments such as surgery or thorax tube were not required. Although rare, pneumothorax should be remembered in any pregnant woman with dyspnea and chest-pain and must be confirmed radiographically to distinguish it from other diseases and conditions. In this report, a case of spontaneous acute pneumothorax and pneumomediastinum in a 10 week primigravida is presented.

Key Words: Pneumomediastinum, pneumothorax, pregnancy

Introduction
Spontaneous acute pneumothorax may occur as a result of spontaneous rupture of subpleural blebs or bullae in a patient with previously healthy lungs(1,2). It is extremely rare during pregnancy and potentially serious for both mother and fetus(3,4). Diagnosis, treatment, follow-up of pregnancy and also the timing and mode of delivery are all problems related to this disease. In this report, we presented a case of acute pneumothorax and pneumomediastinum in a primigravida at 10 weeks of gestation.

Case
A 22-years-old gravida 1, para 0 woman presented at 10th gestational week to the emergency department with the complaints of chest pain and swelling on her neck and upper thorax following 2 days of shortness of breath. She was also suffering from nausea and vomiting almost 6-7 times a day for 2 weeks resulting from hyperemesis gravidarum. She had no history of cough, fever, chills or trauma. She was a non-smoker with no history of pulmonary disease. Her medical history was unremarkable. She had no family history of pulmonary disease. On her physical examination, she was found to...
be mildly tachypneic and her breath sounds were normal. Blood pressure was 100/60 mmHg, pulse rate was 96 beats per minute, respiratory rate was 30 breaths per minute and body temperature was 37.3 °C. Blood gas analysis confirmed normal arterial oxygen and carbon dioxide tension. On palpation, subcutaneous crepitation was noted over the neck. Liver enzymes were mildly elevated. Computed tomography (CT) of the chest was performed with abdominal shield that revealed bilateral pneumothorax and pneumomediastinum. Also, subcutaneous emphysema in neck, upper thoracal and bilateral axillary skin areas were present on CT sections (Figure 1). Nasal oxygen was applied at a rate of 5-6 lt/min during 10 days of hospitalization. Analgesics and antiemetics were used as needed. In order to exclude any esophageal rupture suspected, upper gastrointestinal system endoscopic examination was carried out immediately after the patient’s condition was stabilized. Since physical findings, daily chest x-rays and oxygen saturation were all improved day by day, surgical treatment or thorax tube was not required and only supportive treatment was sufficient. The patient recovered well and was discharged on the tenth day. The patient and her family were advised about her condition and also the risk of recurrence. Therefore they were noted about the importance of regular follow-ups. The patient had elective cesarean delivery because of cephalopelvic disproportion at another hospital at 38th week under spinal anesthesia and gave birth to a healthy male baby. No recurrence of pneumothorax has occurred throughout the gestation.

Discussion

Spontaneous pneumothorax in pregnancy is extremely rare. Rupture of a subpleural apical bulla or bleb, pulmonary lymphangiomatosis and cavitary tuberculosis are the most common cause of spontaneous pneumothorax in pregnancy(3,4). No history of pulmonary lymphangiomatosis or tuberculosis was noted in our patient. Spontaneous pneumothorax occurred during the perinatal period in 53.3% and during the first or second trimester in 46.7% of cases(3). According to the review of 45 cases, the patients were young (average age 26.7±2.3 years) and of low gravidity (mean gravidity 1.7)(3,4). Our patient was also quite young and it was her first pregnancy. Spontaneous pneumothorax occurred at very early stage of her gestation. Our patient presented with chest pain, swelling in neck and dyspnea and she was referred to our university from a town hospital. According to previous reports the most common presenting symptoms of spontaneous pneumothorax in pregnancy were chest pain and dyspnea (3,4). Since she was in the first trimester of pregnancy, chest X-ray had been avoided. However, chest radiographs are necessary to confirm the diagnosis and the potential risk and benefits associated with a radiologic examination must be compared. Ionizing radiation represents a potential risk to the fetus, particularly during the first 8 weeks of development which is the period of organogenesis. Therefore abdomen should be shielded during any radiographic examination. For standard chest radiography with a shielded maternal abdomen, the dose to the uterus is estimated to be 1 mrad per examination. A single series of chest CT scans at 1 cm intervals exposes the conceptus to an upper limit of less than 1 rad, and the actual dose is likely closer to 0.5 rad(5). No increased rates of anomalies have been reported in children exposed to less than 1 rad of ionizing radiation in utero(5). So, it is safe to perform the standard chest radiography when pneumothorax is suspected in a pregnant patient, even during the first trimester, if the abdomen is shielded(6). Shielded computed tomography of thorax was taken right away in our emergency service.

A spontaneous pneumothorax should be considered in the differential diagnosis of chest pain and breathlessness during pregnancy and delivery. The differential diagnosis includes cardiac tamponade, pericarditis, angina pectoris, dissecting aneurysm, mediastinitis, pulmonary embolism and esophageal tear(7). A high index of suspicion is necessary to make the diagnosis and initiate the treatment. In our case, the diagnosis was easily made by CT scan of thorax. Actually standard chest radiography is diagnostic and should be the first step in diagnosis(7).

An underlying infection, asthma history of pneumothorax and cocaine use were considered as risk factors for spontaneous pneumothorax(8). But interestingly, our patient had none of the mentioned risk factors.

Treatment of pneumothorax during pregnancy was controversial. However, recent reports and reviews suggest modern conservative treatments(9,10). Treatment is generally the same as for non-pregnant patients and based on the

Figure 1. Pneumomediastinum and bilateral pneumothorax seen in CT section
size of pneumothorax. Admission and close observation of the patient is usually done in small pneumothorax. Pneumothorax in pregnancy can be treated expectantly provided that the size is small (<2 cm), patient is not dyspneic and no fetal distress is present(9). Since pneumothorax and pneumomediastinum were relatively small in this case and the patient was at a very early stage of her pregnancy, she was managed conservatively. Ten days of supportive treatment consisting of reassurance, oxygen supplement, and analgesics was sufficient for her recovery. If mentioned that conditions are not fulfilled, other treatment options are needle aspiration, needle decompression, pleurodesis, tube thoracostomy, thoracotomy and thoracoscopy for recurrent, persistent or bilateral pneumothorax(9).

The mode of delivery after a pneumothorax is also a matter of worry. According to Tanase et al., allowing spontaneous vaginal delivery after appropriate treatment of pneumothorax during pregnancy seems safe(3). If pneumothorax is diagnosed in a term pregnancy, cesarean section under general anesthesia should be avoided because the positive pressure ventilation can lead to tension pneumothorax(11). The mode of delivery should be selected only for obstetric indications. According to previous literature results, the safest approach for termination is elective assisted deliveries; such as forceps assisted delivery to shorten the second stage of delivery. Even if emergent cesarean section is indicated due to obstetric considerations, it should be performed under spinal anesthesia rather than a general anesthesia(10). In our case, elective cesarean delivery under spinal anesthesia was performed because of cephalopelvic disproportion.

Studies describe an increased risk of recurrence both in pregnancy and during childbirth in patients with pneumothorax(12). The risk of recurrent pneumothorax in these patients is 30%-40% particularly during labor(13). Therefore, in any future pregnancy, delivery should be strongly considered when fetal pulmonary maturity can be documented(12). Also, preconceptual counseling about this risk is vital and women must be advised about potential serious adverse outcomes. Recurrent pneumothorax during pregnancy can be treated in the same way as in non-pregnant women. Prognosis is generally good for both the mother and the baby. Thoracotomy and video-assisted thoracoscopy (VATS) have been increasingly successful procedures for managing patients. There were no maternal or fetal complications reported in those who underwent antepartum surgical intervention(13). No recurrence of pneumothorax occurred in our patient neither during pregnancy nor during cesarean section.

In summary, although rare, pneumothorax should be remembered in any pregnant woman with dyspnea and chest-pain and must be confirmed radiographically to distinguish it from other diseases and conditions. Therapeutical approach is the same as in non-pregnants. Most cases resolve with supportive or just expectant management. Risk of recurrence both in pregnancy and during childbirth is increased in patients with pneumothorax. Therefore, preconceptual counseling must be given to these women.
