ABSTRACT

BACKGROUND: The purpose of this study was to investigate the diagnostic efficiency of multidetector computed tomography (MDCT) in the detection of blunt bowel and mesenteric injuries (BBMI), and the role of different experience levels in using MDCT.

METHODS: This study included a test group of twenty-seven patients with surgically important BBMI in whom the diagnoses were confirmed after surgical intervention (23 men and 4 women; mean age, 40.7±16.2; range, 18-76), and a control group of twenty-one matched patients without BBMI who underwent laparotomy for trauma during the same time period (16 men and 5 women; mean age, 38.9±14.5; range, 20-68) and sixteen-detector computed tomography prior to surgery. Intraoperative findings were compared with MDCT findings.

RESULTS: High accuracy, specificity, and positive predictive values in MDCT findings with respect to intraperitoneal free air, mesenteric air, thickened (>4-5 mm) and defected bowel wall, increased contrast enhancement on bowel wall, and mesenteric hematoma were found among others (p<0.01). Sensitivities and specificities of the diagnosis of BBMI by the resident and staff radiologist was 74% and 71%, and 85% and 100%, respectively.

CONCLUSION: MDCT displays BBMI with high sensitivity and specificity, and can predict the need for surgery. Experience in radiology is an important factor for appropriate interpretation of the MDCT findings.

Key words: Blunt abdominal trauma; bowel injury; multidetector computed tomography.

INTRODUCTION

Blunt bowel and mesenteric injuries (BBMI) are rare injuries with high morbidity and mortality, and occur in only 1-5% of blunt abdominal traumas.[1-4] Accurate diagnosis is of great importance since delayed diagnosis of BBMI may result in serious complications and mortality. Early diagnosis of isolated BBMI is difficult in patients with blunt abdominal trauma as clinically apparent signs and symptoms of peritonitis caused by perforation can be observed only after a considerable period of time, causing delayed diagnosis. As a result of delay in diagnosis, intraabdominal complications, such as abscess, sepsis, and even mortality, can be seen after surgical repair. [1-7] Signs and symptoms of peritonitis like rigidity, tenderness, and rebound are sometimes undetectable, and abdominal examination findings may be obscure in patients critically injured or neurologically compromised or in those experiencing an altered sensorium resulting from drugs, alcohol intoxication, or central nervous system trauma simultaneously. Currently, the diagnostic modalities besides physical examinations are paracentesis, diagnostic peritoneal lavage, focused abdominal sonogram for trauma, computed tomography (CT) scan, and laparoscopy.[7-15] Multidetector computed tomography (MDCT) is an excellent imaging modality for diagnosing and managing patients with abdominal injuries while playing critical role in describing and grading solid-organ injuries, diagnosing the significance of BBMI, and deciding whether surgical
intervention is required. If patients are hemodynamically un-
stable, detection of suspected bowel and mesenteric injuries
is necessary for emergency surgical treatment.[4-7] However, if
patients are hemodynamically stable and no suspicious BBMI
is present on MDCT, nonsurgical management is the accept-
able standard care for blunt abdominal trauma. However, the
true contribution of MDCT in diagnosing BBMI is controver-
sial.[16,17] there is a wide spectrum of signs correlating with
the type, site, and extent of damage on CT.[4] Although CT
imaging technology and interpretation has improved greatly
in the past decade in terms of detection or exclusion of BBMI,
controversy still remains as to how reliable MDCT is in dis-
tinguishing surgical from nonsurgical bowel and mesenteric
injury.[5]

The main goals of this study were to investigate the diagnostic
accuracy of MDCT in the detection of bowel and mesenteric
injuries, and evaluate the concordance of MDCT findings of
BBMI with surgical observations and with different experi-
ence levels in radiology.

MATERIALS AND METHODS

The ethics committee of our hospital approved this retro-
spective case-control study and waived the requirement for
informed patient consent.

Patients

Totally, two thousand nine hundred and twenty-three pa-
patients with blunt abdominal trauma between January 2007
and December 2012 were enrolled. The test group com-
prised twenty-seven patients with surgically important BBMI
whose diagnoses were confirmed after surgical intervention
(23 men and 4 women; mean age, 40.7±16.2 years; age
range, 18-76 years). The control group comprised twenty-
one matched patients without BBMI who underwent lapa-
rotomy for trauma during the same time period (16 men and
5 women; mean age, 38.9±14.5 years; age range, 20-68 years)
and sixteen-detector computed tomography prior to surgery.
Intraoperative findings were compared with MDCT findings.

MDCT Technique and Interpretation

MDCT scans were obtained using a 16-row multidetector CT
scanner (Aquilion 16; Toshiba Medical Systems Corporation,
Japan). The scanning parameters were as follows: 150 mAs;
120 kV; collimation, 2x16 mm; pitch, 1; section thickness, 3
mm; reconstruction interval, 1 mm; and tube rotation period,
0.5 s. Intravenous iodinated contrast was given according to
protocol: 100-120 ml of 350 mg/ml contrast at 3 ml/s. Oral
contrast (OC) was not used routinely due to current con-
troversy on using OC in trauma patients. OC use in trauma
patients may sometimes cause cervical restraints, a supine
position, intoxication, diminished sensorium, nausea, vomit-
ing, need for a nasogastric tube, risks of aspiration, and time
constraints with limited visualization of the intestinal tract[10];
only five patients were administered OC in this study. For
single-phase imaging, post-contrast images of the abdomen
and pelvis were acquired at 70 s. When necessary, sagittal
and coronal images were acquired using the multiplanar re-
construction technique. Scans were also evaluated using the
“lung or bone” windows that helped differentiate between
abdominal fat and air.

In order to assess the accuracy of different levels of experi-
ence on radiology, all CT scans were reevaluated indepen-
dently by a fourth-year radiology resident and a staff abdomi-
nal radiologist, both of whom were blinded to the patients’
final outcomes and the initial radiological reports. All evalua-
tions were reviewed using our department’s picture archiving
and communicating system on liquid crystal display monitors,
and the probability of BBMI was recorded. Coronal and sagit-
tal CT reconstructions were available for review, if necessary.
Numerous CT signs of bowel and mesenteric injury second-
ary to blunt trauma have been described in the literature, and
our CT findings were based on these descriptions.[17, 18] CT
signs of BBMI are intraperitoneal air, retroperitoneal air, mes-
enteric air, thick bowel wall, abnormal bowel wall enhance-
ment, bowel wall defect, intraperitoneal fluid, retroperitoneal
fluid, focal mesenteric hematoma, mesenteric fluid, and mes-
enteric stranding.

Statistical Analyses

The X² test was used for the comparison of categorical vari-
ables; the Wilcoxon rank-sum test was used for the compari-
son of continuous variables. Sensitivity, specificity, and posi-
tive and negative predictive values were calculated for each
reader and each MDCT sign. For evaluating concordance of
the diagnoses of BBMI by the two readers, kappa ratio was
calculated for each reader. According to the criteria of Lan-
dis and Koch,[19] a kappa value of less than 0 indicated less
agreement than expected by chance; 0-0.20, slight agreement;
0.21-0.40, fair agreement; 0.41-0.60, moderate agreement;
0.61-0.80, substantial agreement; 0.81-0.99, almost perfect
agreement; and 1.0, perfect agreement. Positive and negative
likelihood ratios were calculated for individual MDCT signs. A
value of p<0.05 was considered to be significant.

RESULTS

Twenty-seven (56%) of 48 patients had surgically proven
BBMI and 21 (44%) patients had no BBMI. The BBMI rate
detected on MDCT in our study was 0.9% (27/2923). Of the
twenty-seven patients with BBMI, 20 (74%) had bowel injury,
3 (11%) had mesenteric injury, and 4 (15%) had bowel and
mesenteric injury. The localizations of bowel injury were the
ileum, 12 (50%); jejunum, 6 (25%); colon, 3 (13%); jejunum-
ileum, 2 (8%); and ileum-colon, 1 (4%). Forty-two (88%) pa-
tients had been involved in a motor vehicle accident. Of the
remaining six injuries, four resulted from falls and two form
industrial accidents. Peritoneal lavage was not performed for
any of the patients. OC was not used routinely; only five patients were given OC in our study.

Sensitivities of the resident and staff radiologist in the diagnosis of bowel and/or mesenteric injury ranged from 74% to 85% and the specificities ranged from 71% to 100%; false-negative case numbers were 9 and 4 and false-positive case numbers were 2 and 0, respectively (Fig. 1).

High accuracy, specificity, and positive predictive values for MDCT findings in terms of intraperitoneal free air, mesenteric air, thickened (>4-5 mm) bowel wall, increased contrast enhancement on bowel wall, bowel wall defect, and mesenteric hematoma were found among others (Table 1). Intraperitoneal free air (Fig. 2a), mesenteric air (Fig. 2b), thick large bowel (Fig. 2c), increased bowel wall enhancement (Fig. 2c), bowel wall defect (Fig. 2d), focal mesenteric hematoma, and mesenteric fluid and mesenteric stranding (Fig. 2e) showed the best positive likelihood ratios for bowel and/or mesenteric injury. MDCT findings, reviewed by the staff radiologist, were given in Table 2 according to the injury type. The differences in detecting BBMI were statistically significant among readers evaluating inter-observer agreement between reviewers (p<0.01). In case of the staff radiologist, the concordance of the CT findings and operative findings was excellent (kappa ratio: 0.834 [0.81-1, excellent]).

DISCUSSION

MDCT significantly affects the decision on managing non-operative patients without BBMI but with isolated solid-organ injuries. However, the diagnosis of patients with suspected BBMI after blunt trauma is a dilemma and clinical diagnosis of BBMI and differentiation of those requiring surgery from those that can heal clinically is the main problem.[16,17]

Although CT is the best noninvasive modality presently available to diagnose BBMI, several studies report that only CT is unreliable in diagnosing BBMI.[5,10,17] Sharma et al. reported that BBMI was not initially diagnosed in 35% (8 of 23) of the patients.[10] Bhagvan et al.[17] stated that the false-negative CT scan incidence was 13% in five hundred and fifty-eight patients with small bowel perforation. It is considered necessary to conduct an urgent exploration for any unexplained and nonspecific CT scan findings in patients with more than one suspicious finding for bowel or mesenteric injury on the CT scan due to the possibility of false negativity.[10] In our study, the false-negative rate was 14.8% (4/27) for the staff radiologist and 33.3% (9/27) for the radiology resident. In terms of evaluations of CT findings, in this study, high accuracy, speci-

PPV: Positive predictive value; NPV: Negative predictive value. *: This likelihood ratio is considered useful in clinical practice.
ficity, and positive predictive values in terms of intraperitoneal free air, mesenteric air, bowel wall thickening, and increased contrast enhancement on bowel wall, bowel wall defect, and mesenteric hematoma were found among others.

Besides the difficulty in performing a CT diagnosis, it warrants optimal technique and skilled interpretation. Atri et al. have found that the staff radiologist is significantly more accurate than the resident in identifying mesenteric injuries (p<0.01). In case of surgically important bowel injuries, significant differences were observed between the sensitivity and specificity values of the staff radiologist and those of the trainees (resident and fellow). [4] In the present study, the difference in detecting BBMI in terms of sensitivity and specificity were statistically significant between the two readers (p<0.01). The concordance of the CT findings with the operative results was excellent in the case of the experienced radiologist (kappa ratio: 0.834).

Several studies report on discrepancies in CT interpretations by residents and staffs. Tieng et al. have reported a 10% discrepancy rate. [20] Yoon et al. [21] have found a 29.9% discrepancy rate in their study. In this study, the false-negative rates were 8.3% (4/48) for the staff radiologist and 18.75% (9/48) for the resident. The staff radiologist had no false-positive rate but the resident had two false positives (4%, 2/48) in our cohort. While our discrepancy rate is moderate at 14.6%.

(7/48), it cannot be guaranteed in the current practice. Even one case is very important and if it were to be concluded, a terrific result would have occurred due to this discrepancy. As in many countries, in our institute, general workflow in terms of daily practice is the interpretation given at night by residents. After this initial resident interpretation, secondary review is performed by a staff radiologist within 24 h. This delay may sometimes cause mortality; teleradiology may be a solution for preventing this kind of time delay and consulting with experts during off-hours.

Teleradiology interpretations may assist emergency physicians in making appropriate medical decisions and radiology residents provide initial readings and prevent discrepancies during off-hours. Teleradiology is defined as the electronic transmission of radiographic images between two geographical locations for the purposes of interpretation and consultation. In countries with picture archiving and communication system (PACS) integrated in a regional or national network, image distribution can be organized in a cross-enterprise fashion. In many European countries and in the United States, a large teleradiology network has been established and the DICOM-email is the accepted standard. In several hospitals, teleradiology has become a part of the regular workflow. Image distribution using PACS support home-based (on call) radiologists in emergency situations.[21,23]

There are several limitations to this study. It was retrospective; patients of a specific period of time were reviewed and only patients with blunt abdominal trauma were evaluated. In addition, the CT finding readers were aware of the patients surgically treated but were blinded for the surgical reports; this might have forced the readers to try to find a pathological finding on the CT scans. However, since the staff and resident were informed of the cases in the same manner, no differences existed in the distribution of information to both readers. Moreover, as the CT findings were compared with operative findings, only surgically treated patients were included into the study. In addition, this study included a small number of surgically proven BBMI cases.

Experience in radiology is an important factor causing differences in the interpretation of CT findings and making CT examination more sensitive and specific in terms of decision-making on the clinical management (surgery or nonsurgical follow-up). Awareness of BBMI findings on CT scans and experience increase the diagnostic accuracy of CT. However, diagnosis of BBMI is difficult and CT cannot be used as the only diagnostic tool. Close clinical observation, monitoring, and surgical expertise are mandatory for appropriate management. Teleradiology may help in reporting cases from out of hospital and may help to avoid discrepancies. Further studies are needed to better define the sensitivity of teleradiological interpretations for identifying the pathology of trauma.

Conflict of interest: None declared.

AMAC: Çalışmamızda künt bağırsak ve mezenter yaralanmalarında (KBMY), çok kesitli bilgisayarlı tomografinin (ÇKBT) tanısal etkinliğinin ve farklı düzeydeki radyolog tecrübesinin tanıya katkısının değerlendirilmesi amaçlanmıştır.

GEREÇ VE YÖNTEM: Çalışma grubuna travma nedeniyle cerrahi uygulanan ve klinik önemi KBMY olduğu doğrulanmış ve ameliyat öncesi BT inceleme bulunan 27 hasta (23 erkek, 4 kadın, ort. yaş 40.77±16.2 yıl; dağılım 18-76 yıl) alındı. Kontrol grubu olarak da yine aynı dönemde BT inceleme bulunan ve cerrahi sonrası KBMY olmadığı doğrulanmış 21 hasta (16 erkek, 5 kadın, ort. yaş 38.9±14.5; dağılım, 20-68) alındı. Cerrahi öncesi 16 kesitli ÇKBT ile yapılan inceleme her biri bilinmeksizin tekrar yorumlandı. ÇKBT bulguları ameliyat bilgileri ile karşılaştırıldı.

BULGULAR: Çok kesitli bilgisayarlı tomografik bulgular ile intraperitoneal serbest hava, mezenterik hematom, bağırsak duvarında kalınlık artış, bağırsak duvarında kontrast alınma artışı, bağırsak duvarında defekt ve mezenterik hematom bulgusu, doğruluk, özgüllük ve pozitif öngörü değer bakımından yüksek bulundu (p<0.01). KBMY doğru tanı koyabilen radyolojik asistan ve abdomen tecrübeli radyolog arasında etkisi farklı bulunmadı. Radyolojideki tecrübe ÇKBT’nin doğru raporlanmasında önemli bir faktördür.

TARTIŞMA: Çok kesitli bilgisayarlı tomografik, KBMY’yi yüksek duyarlılık ve özgüllük ile gösterebilir ve künt karın travması için önemi bir faktördür. Anahtar sözcükler: Bağırsak yaralanması; çok kesitli bilgisayarlı tomografik, künt karın travması.
