Introduction

We present the case of a woman with hepato-renal polycystic disease and chronic hemodialysis admitted for paroxysmal atrial fibrillation. A right heart mass was diagnosed by echocardiography. MRI and angio-CT scans confirmed a calcified tumor with the origin in the right internal iliac vein that extended through inferior vena cava to the right cardiac chambers. The intracardiac tumor was excised by cardiovascular surgery due to perceived pulmonary embolic risk. The tumor mass was a leiomyoma. Despite extensive inferior vena cava extension, tumor dimensions did not increase at one year follow-up and no intracardiac recurrence was noticed.

Case Report

A 55-year-old woman with hepatorenal polycystic disease and end-stage renal failure who was on chronic hemodialysis was admitted to our center because of a recent history of dyspnea and palpitations.

Physical examination revealed wide splitting of the first heart sound and an enlarged liver and left kidney. Bilateral mild edema of the calves was observed. A 12-lead electrocardiogram (ECG) showed paroxysmal atrial fibrillation. Blood tests revealed high creatinine and blood urea nitrogen levels due to severe chronic kidney failure (serum creatinine=10.4 mg/dL).

Transthoracic echocardiography showed a large, polylobulated, echogenic, highly mobile mass that occupied most of the right atrium and prolapsed through the tricuspid valve during diastole (Fig. 1 and angiographic run in Video 1, 2).

Cardiac magnetic resonance imaging (MRI) failed to reveal if the observed mass represented thrombus or the terminal part of an intravascular tumor (Fig. 2).

CT angiography (angio CT) showed a large, polylobulated, echogenic, highly mobile mass that occupied most of the right atrium and extended from the inferior vena cava (IVC) and prolapsed into the right ventricle through the tricuspid valve during diastole (Fig. 1 and angiographic run in Video 1, 2).

Cardiac magnetic resonance imaging (MRI) failed to reveal if the observed mass represented thrombus or the terminal part of an intravascular tumor (Fig. 2).

CT angiography (angio CT) showed an extensive, serpiginous, highly vascularized mass originating in the right internal iliac vein, which extended to IVC up to the right cardiac chambers. Massive linear calcifications were seen along IVC and above the renal veins (confirmed by angiography run in Video 2). Cystic transformation of the liver and kidneys was extensive. The right kidney was ectopic and occupied most of the pelvis (Fig. 3). No pulmonary artery embolus was noticed.

Coronary angiography showed calcified coronary atherosclerosis, but no significant obstructive coronary artery disease.

Figure 1. Transthoracic echocardiography, four-chamber view: a large polylobulated echogenic and highly mobile mass occupies most of the right atrium and prolapses through the tricuspid valve and remains trapped in systole (red arrows; RV, RA - right ventricle and right atrium; LV, LA - left ventricle and left atrium)

Figure 2. Cardiac MRI cine-gradient short-axis view: a hypointense structure (thrombus or tumor) extends from the inferior vena cava to the right atrium (red arrows)
At one-year follow-up, the patient was asymptomatic, and the tumor remained confined to IVC. The patient refused to undergo a second surgery due to the additional risks involved.

**Discussion**

Intravascular leiomyomatosis is a rare disorder that consists of smooth muscle cell proliferation within vascular spaces. Although it is a benign tumor, its outcome may be severe due to the extension pattern. It is usually due to a uterine leiomyoma which extends into the uterine venules and from there into IVC and upward (1). Rarely, as in the case of this patient, it originates directly from the smooth muscle cells of the walls of the internal iliac vein or IVC. Although it is cytogenetically similar, a monoclonal origin distinguishes intravascular leiomyomatosis from multiclonal uterine leiomyomas (2). As the smooth muscle...
cells of intravascular leiomyomas express estrogen and progesterone receptors, it was presumed that tumor growth might respond to hormonal manipulation. However, literature data is inconclusive, and hormonal therapy needs further evaluation (3). The association between polycystic kidney disease and leiomyomatosis is highly intriguing and was reported in rats as a consequence of the somatic loss of function of the tuberous sclerosis-2 tumor-suppressor gene (4). In humans, the cytogenetic and molecular characteristics of intravascular leiomyomas have yet to be fully described.

**Conclusion**

We describe a case of intravascular leiomyomatosis with extension from the internal iliac vein to IVC and right heart chambers, which was symptomatic by paroxysmal atrial fibrillation. Significant comorbidities such as polycystic hepatorenal disease and chronic hemodialysis were associated. Successful cardiac mass resection was not followed by recurrence at one-year follow-up.

**Biventricular non-compaction cardiomyopathy with pulmonary stenosis, interatrial septal aneurysm, atrial septal defect, bradycardia, and mental retardation in a single case:**

A case report

**Introduction**

Non-compaction cardiomyopathy is a rare myocardial disease that belongs to the non-classified congenital cardiomyopathies (1). Although the left ventricle is mainly affected, biventricular involvement has also been described in recent years (2). The clinical features of non-compaction cardiomyopathy are non-specific and can range from being asymptomatic to symptoms of arrhythmia, thromboembolism, and congestive heart failure (2). Non-compaction cardiomyopathy is a complicated disease that can be isolated or be associated with other anomalies, and these patients can present with concomitant pathological findings, including obstructive ventricular anomalies (3, 4), mitral cleft (5), ventricular septal defect (6), and atrial septal defect (7). In 2008, Wessels et al. (8) described a three generation family with nine patients affected by a combination of cardiac abnormalities and left isomerism. The cardiac anomalies included ventricular non-compaction (mostly biventricular), secundum atrial septal defect, pulmonary valve stenosis, and conduction defects. The laterality sequence anomalies included left bronchial isomerism, azygous continuation of the inferior vena cava, polysplenia, and intestinal malrotation, all compatible with left isomerism (8). The authors described these individuals as a member of a new syndrome, which is inherited in an autosomal dominant pattern. A genome-wide linkage analysis suggested a linkage to chromosome 6p24.3–21.2 with a maximum LOD score of 2.7 at the marker D6S276. The linkage interval was located between the markers D6S470 (telomeric side) and D6S1610 (centromeric side) and overlapped with the linkage interval in another family with heterotaxy (8). Herein, we report a 45-year-old woman who had moderate mental retardation and biventricular non-compaction cardiomyopathy in association with other congenital heart malformations.

**Case Report**

A 45-year-old woman with moderate mental retardation presented to the hospital with dyspnea and cyanosis as the first man-
