An adult patient with the ruptured aneurysm of mitral valve posterior leaflet

A 34-year-old man was admitted to our hospital with exertional dyspnea. Past medical history was significant for asymptomatic mitral valve prolapse, moderate mitral regurgitation and chordae tendinea rupture diagnosed two years previously. He had no history of palpitation or fever. Physical examination revealed apical 3/6 grade systolic murmur. Electrocardiography was in normal sinus rhythm. 2D and 3D trans-thoracic echocardiography (TTE) showed that left ventricular ejection fraction was 67%, left heart chambers were dilated and a saccular aneurysm bulging towards the left atrium at the posterior mitral leaflet. In color Doppler examination, there was a regurgitant flow across the aneurysm, suggesting rupture. (Fig. 1A and Video 1. See corresponding video/movie images at www.anakarder.com) There was no evidence of infective endocarditis. Real-time three-dimensional transesophageal echocardiography (RT3D TEE) confirmed the TTE findings. In addition, it revealed the bulging into the left atrium was in both systole and diastole, confirming the diagnosis of aneurysm instead of prolapse. (Fig. 1B, C, 2A, B, 3A, B and Video 2, 3, 4. See corresponding video/movie images at www.anakarder.com). The patient was scheduled to elective surgical operation.

Structural failure of a left atrial appendage occluder device

Structural failure of left atrial appendage (LAA) occluder devices is rarely reported. An 81-year old female patient was implanted with a...
**Fistulous connection of left circumflex coronary artery to coronary sinus presenting with massive pericardial effusion**

Büyük perikardiyal efüzyon ile ortaya çıkan sol sirkumflex koroner arterin fistül ile koroner sinüse bağlantısı

Coronary arteriovenous fistula is a rare anomaly through which the involved coronary artery flow drains into a cardiac chamber, great vessel, or other structures, bypassing the myocardial capillary network. The right coronary artery and the right ventricle are the most common origin and distal connection sites, respectively. A left circumflex artery with a fistulous connection to the coronary sinus is extremely rare.

In this report, we presented an extremely rare case of left circumflex coronary artery-coronary sinus fistula associated with restricted sinus opening to right atrium presenting with non-bloody massive pericardial effusion that was probably caused by abnormal pericardial veins drainage. A 43-year-old male was referred to our department because of progressive exertional dyspnea during the past 3 months with no risk factor for coronary artery disease. Transthoracic echocardiography showed massive circumferential pericardial effusion, marked dilatation of coronary sinus and multiple echo-free spaces adjacent to left atrioventricular groove (Fig. 1A, B. Video 1, 2. See video/movie images at www.anakarder.com) and (Fig. 1B). Transesophageal imaging with color Doppler flow revealed multiple echo-free spaces with visible flow adjacent to dilated coronary sinus and left circumflex artery. There was aneurysmal dilatation of coronary sinus (5 cm) filled with intramural thrombus and significant narrowing (1-2 mm) with turbulent flow at its opening to the right atrium (Fig. 2A Video 3, 4. See video/movie images at www.anakarder.com) with high velocity continuous Doppler signal (Fig. 2B). A preoperative cardiac catheterization showed aneurismal dilation and severe tortuosity of left circumflex coronary artery draining into the coronary sinus (Fig. 3). On the basis of these findings, a final diagnosis of coronary artery fistula to the aneurismal coronary sinus was made. The patient underwent surgical treatment under cardiopulmonary bypass. If left untreated, the coronary sinus aneurysm in the present case might have ruptured spontaneously.

**Figure 1.** A) Perioperative echocardiography after WATCHMAN left atrial appendage occluder implantation. Notice absence of membrane gap and absence of flow into the left atrial appendage. A) and (C) One-month follow-up echocardiography showing a gap within the left appendage occluder device membrane (red arrow) with persistence of blood flow within the left atrial appendage D) Three-month control echocardiography showing closure and endothelialization of the device (red arrow)

WATCHMAN LAA system. An intraoperative echocardiography control showed perfect position of the device and absence of flow within the LAA (Fig. 1A). The patient was discharged on dual antiplatelet therapy. Oral anticoagulation was omitted being the patient at prohibitive risk for cerebral bleeding. At a one-month follow-up the device remained with good anchoring and position but a discontinuity of its membrane was noticed (Fig. 1B) allowing for persistent flow within the LAA (Fig. 1C). In spite of the increased risk of thromboembolism, no further intervention was planned in the hope that the membrane gap would have endothelialized spontaneously. A three-month follow-up echocardiography confirmed complete endothelialization and closure of the occluder without residual LAA flow (Fig. 1D).

When a membrane rupture is present, the communication between LAA and left atrium persists with increased risk of thrombus formation and embolism. This eventuality may be even increased in patients with contraindication to anticoagulation. If the membrane gap is limited in size, spontaneous closure may happen as herein reported. In any case caution must be advocated to perform appropriate monitoring of those patients where suspect of LAA structural failure has been documented. Moreover, the risk of recurrent cerebrovascular events should be pondered.

The case demonstrates that the LAA closure is relatively safe and effective. However, severe complications can occur. It might become an alternative for atrial fibrillation patients who are ineligible for long-term anticoagulation therapy.
