

A Rare Cause of Massive Pulmonary Hemorrhage: Invasive Actinomyces

Masif Pulmoner Hemorajinin Nadir bir Nedeni: İnvaziv Aktinomikoz

Abstract

Pulmonary actinomyces is a severe clinical condition that may cause death if unrecognized. It may occur in patients who were previously healthy or may develop in patients with chronic immunosuppressant conditions. Presently described is a rare case of massive pulmonary hemorrhage with a related angioinvasive Actinomyces infection. A 52-year-old formerly immunocompetent man was admitted to the hospital due to blood-streaked sputum. A computed tomography image of the thorax taken after the patient's clinical status suddenly worsened revealed total collapse of the left lung. No tumoral lesion was observed, but extensive necrosis of the mucosa of both main bronchi with massive hemorrhage in the left main bronchus was noticed in an urgent bronchoscopy performed in the intensive care unit. A histopathological examination of the mucosal punch biopsy demonstrated aggregates of filamentous Gram-positive organisms indicating Actinomyces infection.

Özet

Pulmoner aktinomikoz geç tanı konulduğunda ölümle sonuçlanabilecek bir durumdur. Daha çok immün yetmezliği olan bireylerde beklendiği gibi immün-kompetan kişilerde de görülebileceği unutulmamalıdır. Bu yazıda invaziv pulmoner aktinomikozla bağlı masif pulmoner hemoraji gelişen nadir bir olgu sunulmuştur. Elli iki yaşında bilinen immünsupresif durumu olmayan erkek hasta ağızdan balgamla karışık kan gelmesi nedeni ile yatırıldı. Elektif bronkoskopi planlanan hastanın genel durumunda ani kötüleşme nedeni ile çekilen toraks bilgisayarlı tomografisinde sol akciğerde başvuruda olmayan total ateletazi saptandı. Yoğun bakım ünitesinde yapılan acil bronkoskopide sol ana broşta masif hemoraji ve her iki ana bronş mukozasında yaygın nekrotik görünüm izlendi. Alınan mukozal biyopsinin patolojik incelemesinde aktinomikozla uyumlu gram pozitif filamentöz bakteri agregatları izlendi. Bronşiyal arter kateterizasyonunda ekstrasvazasyon saptanan artere

Selective embolization of a branch of the feeding artery was successful to control the hemorrhage, but necrotizing pneumonia emerged and the patient could not be discharged from the intensive care unit. He was later lost despite 40 days of treatment with intravenous penicillin-G plus antifungal therapy. Pulmonary angioinvasive infections like actinomycosis must be kept in mind in the absence of bronchial carcinoma or other frequently encountered diseases in cases of massive pulmonary hemorrhage.

Key words: *Actinomycosis, massive pulmonary hemorrhage, necrotizing pneumonia.*

Actinomycosis is a chronic granulomatous infection of the lung parenchyma caused by *Actinomyces* species. These bacteria form aggregates of Gram-positive, branching, filamentous bacilli, usually found in hard, macroscopic grains of pus called "sulfur granules." *Actinomyces* spp. naturally reside on the mucosal surfaces of healthy individuals. They gain access to deeper tissues via trauma, surgical procedures, prosthetic devices, or foreign bodies, and manage to overcome the mucosal barrier and the immune system (1).

This report is a description of a case of pulmonary actinomycosis with massive pulmonary hemorrhage and fatal necrotizing pneumonia.

CASE

A 52-year-old male was admitted to the hospital for blood-streaked sputum, which had been present for several days. He had no history of a prediagnosed medical condition. He was a heavy smoker and habitual drinker. The patient was afebrile, with a heart rate of 78 beats/minute, a respiratory rate of 22 breaths/minute, and a blood pressure of 110/70 mmHg on initial examination. His arterial oxygen saturation was 93% while breathing room air. A general physical examination revealed cachexia and poor oral hygiene. Cardiovascular examination was normal. Thoracic auscultation on both sides of the lungs was normal, with no added breath sounds. Examinations of other organ systems were normal. His leucocyte count was 10,500 cells/ μ L with a neutrophil predominance. The level of acute phase reactants was not elevated.

A computed tomography (CT) scan of the chest revealed a ground-glass opacity in the left upper lobe, indicating hemorrhage (Figure 1).

Prior to bronchoscopy, the patient experienced sudden chest pain and was transferred to the intensive care unit due to acute respiratory failure. His oxygen saturation

decreased to 44%. An urgent CT revealed total collapse of the left lung (Figure 2). A therapeutic bronchoscopy was performed and the active hemorrhage in the left main stem bronchus was terminated. Selective ventilation of the right lung with a double-lumen endotracheal tube provided adequate oxygenation, and arterial oxygen saturation of 96% was achieved. Selective cannulation and embolization of a branch of the truncus thyrocervicalis, which was responsible for the bleeding, was performed.

A second diagnostic bronchoscopy revealed no tumoral lesion but extensive necrosis of the distal trachea and the main bronchi mucosa (Figure 3). A histopathological examination of the mucosal punch biopsy sample demonstrated aggregates of filamentous Gram-positive organisms, indicating actinomycosis (Figure 4). Microbiological culture isolates failed to identify the bacteriological species because the specimens were not incubated in anaerobic conditions. Bronchial lavage fluid was sent to the laboratory for both direct microscopic investigation

and mycobacterial culture. In addition, polymerase chain reaction analysis for mycobacteria was performed. There was no bacterial growth on Löwenstein-Jensen medium after incubation for 45 days.

Figure 3: Bronchoscopic sections showing extensive necrosis of bronchial mucosa

Figure 4: Aggregates of filamentous gram-positive organisms surrounded by inflammatory cells indicating *Actinomyces*

Serum immunoglobulin levels were tested for HIV infection and tumor markers, and serum and urine analysis was examined for multiple myeloma. The departments of internal medicine and hematology were consulted. Further invasive investigations, such as a bone marrow biopsy, could not be performed due to the poor health status of the patient.

Despite intravenous administration of penicillin-G, necrotizing pneumonia developed in the opposite lung (Figure 5). Antifungal treatment was added for possible co-existing fungal infection. Surgery was not considered due to diffuse infiltrates in both lung fields. The patient was lost after 40 days of treatment in the hospital.

Written informed consent was obtained from the parents of the patient for this case presentation.

DISCUSSION

Actinomyces is a rare cause of pulmonary infection and can be difficult to diagnose because its presentation may

mimic tuberculosis (2) or lung cancer (3). Although individual papers describe infection of almost all tissues of human body, pulmonary actinomyces represents approximately 15% of all cases (4). The most common clinical symptoms of pulmonary actinomyces are chest pain, a productive cough, and hemoptysis. Subacute presentation of constitutional symptoms, like weight loss, fatigue, or fever, may also concur. In our case, the ground glass opacity in the left upper lobe, smoking history, and massive hemorrhage first suggested bronchogenic carcinoma in the differential diagnosis.

Figure 5: Bilateral consolidations showing necrotizing pneumonia during treatment with penicillin G

Actinomyces infections may affect individuals of all age groups, even children, but the most commonly affected group is middle-aged males. Comorbid conditions like diabetes mellitus, smoking or alcohol abuse, poor oral hygiene or periodontitis, gastrectomy, foreign body aspiration like a fish bone, prosthetic devices like a bronchial stent, and healed pulmonary tuberculosis have been reported in the literature, but immunocompetent patients are more commonly affected unexpectedly. Alcoholics with poor oral hygiene, as in our case, are more susceptible to suppurative infections due to aspiration of oral flora, including *Actinomyces* spp. (5). A history of choking must be investigated when no other reason seems to be responsible for the condition.

The most common radiological findings are a mass, nodule, or consolidation on a chest CT (6). Almost all cases need pathological confirmation of actinomyces from lung tissue. In a review article, invasive procedures were performed in 23 patients, of whom 14 underwent a wedge resection or lobectomy, 5 underwent a percutaneous transthoracic lung biopsy, and a bronchial biopsy was performed on 4 (7). Anaerobic cultures are required if there is a suspicion of *Actinomyces* infection, and collections must be made properly in order to identify the pathogens. In our case, the material collection and transport was not appropriate for anaerobic agents, so microbiological isolation of the *Actinomyces* species was not possible.

Although *Actinomyces* spp. are susceptible to several antibiotics the most commonly used agent is parenteral penicillin-G, followed by the oral form. The average duration of treatment is 4 to 5 months (8). Diagnosis or treatment of pulmonary *actinomycosis* usually requires surgical intervention (9). Although surgery seems to be the best treatment modality (10), less invasive techniques, like embolization of the related artery in selected cases with hemorrhage, might be favorable due to fewer complications. Surgery was not the treatment of choice in the present case because the infection had affected many areas of the lung.

CONCLUSION

Although rare, pulmonary *Actinomyces* infection can be life threatening, especially in cases with massive hemorrhage. It must be kept in mind in the differential diagnosis of massive or non-massive hemoptysis or pulmonary hemorrhage, especially in the absence of a tumor or other common causes of bleeding.
