

Diffuse Alveolar Hemorrhage After Intravenous Thrombolysis for Acute Ischemic Stroke

Akut İskemik İnmede İntravenöz Tromboliz Sonrası Diffüz Alveoler Kanama

Keywords: Diffuse alveolar hemorrhage, thrombolysis, stroke
Anahtar Kelimeler: Diffüz alveoler kanama, tromboliz, inme

Dear Editor,

A 37-year-old left-handed woman was brought to the Emergency Department 90 minutes after acute-onset left hemiplegia and global aphasia. Her medical history revealed that she had mitral stenosis and atrial fibrillation for several years. No medications including blood thinners were reported. The initial neurologic examination revealed left hemiplegia, global aphasia, and left gaze preference. A National Institutes of Health Stroke Score of 19 points was recorded. Initial brain computed tomography (CT) excluded bleeding. The CT scan showed a hyperdense abnormality within the proximal right middle cerebral artery (MCA) (Figure 1). CT angiography of the cervical vessels was reported as normal. The initial laboratory findings were within normal limits. The cause of stroke was accepted as cardioembolism due to valvular atrial fibrillation. After obtaining consent, the patient was transferred to the stroke unit for treatment; we infused a standardized protocol of intravenous-recombinant tissue-plasminogen activators (IV-rt-PA) at 2.5 hours after symptom onset with no medical improvement in return. A follow-up brain CT scan at the 24th hour showed a large ischemic lesion demonstrating right MCA M1 occlusion in the right hemisphere (Figure 2).

Twelve hours after the rt-PA treatment, the patient gradually developed dyspnea, cough, hypoxemia, and hemoptysis. A chest X-ray revealed bilateral alveolar infiltrates (Figure 3). The patient underwent endotracheal intubation for mechanical ventilation. Chest X-ray and chest CT on the next day showed bilateral diffuse alveolar infiltrates (Figure 4). The hemoglobin level dropped from 11.6 g/dL to 8.2 g/dL. Diffuse alveolar hemorrhage was suspected and confirmed after a pulmonary

medicine consultation. She received 4 units of fresh frozen plasma and 2 units of packed red cells. The patient remained intubated and on mechanical ventilation for 10 days. Follow-up chest CT and X-ray imaging taken after one month showed complete resolution of the infiltrates. The patient was transferred to the palliative care unit at one month after administration with a modified Rankin scale score of 5.

Diffuse alveolar hemorrhage is a very rare, life-threatening complication of iv. lytic therapy and should be considered in patients with hemoptysis, pulmonary infiltrates, and acute anemia after thrombolysis (1). There are some reports related to alveolar hemorrhage with thrombolytic therapy after myocardial infarction (2,3). This is the first case of pulmonary alveolar hemorrhage in a patient with stroke after thrombolytic therapy.

The exact incidence of this complication is unknown. It usually occurs within a few hours to five days after the thrombolytic treatment. There are some predisposing factors related to intra-alveolar hemorrhage including immunodeficiency, pneumonia, chronic obstructive pulmonary disease, congestive heart failure, and tobacco and cocaine use (3,4). In our patient, hemoptysis started 12 hours after the treatment and none of abovementioned predisposing factors existed. On the other hand, the patient had atrial fibrillation and mitral stenosis associated with rheumatic fever. The presence of alveolar bleeding in this patient might be related to valvular atrial fibrillation.

Management of diffuse alveolar hemorrhage consists of treatment of respiratory failure and anemia (5). Sometimes respiratory failure may require ventilation, as the anemia requires transfusion of packed cells. Our patient required mechanical ventilation for 10 days, and packed red cell transfusions were given twice.

Ethics

Informed Consent: Written informed consent was received from the patient for publication of this report and accompanying images.

Peer-review: Externally peer-reviewed.
